Bayesian Networks: Definition and Assumptions

Continuous-Time Bayesian Networks

Bayesian Networks for Structured Data

Future Directions
A Bayesian network (BN) [20] is defined by:

- a network structure, a directed acyclic graph $\mathcal{G}$ in which each node corresponds to a random variable $X_i$;
- a global probability distribution $\mathbf{X}$ with parameters $\Theta$, which can be factorised into smaller local probability distributions according to the arcs present in $\mathcal{G}$.

The main role of the network structure is to express the conditional independence relationships among the variables in the model through graphical separation, thus specifying the factorisation of the global distribution:

$$P(\mathbf{X}) = \prod_{i=1}^{N} P(X_i \mid \Pi_{X_i}; \Theta_{X_i})$$

where $\Pi_{X_i} = \{\text{parents of } X_i \text{ in } \mathcal{G}\}$.
Learning a BN $\mathcal{B} = (\mathcal{G}, \Theta)$ from a data set $\mathcal{D}$ involves two steps:

$$P(\mathcal{B} \mid \mathcal{D}) = P(\mathcal{G}, \Theta \mid \mathcal{D}) = P(\mathcal{G} \mid \mathcal{D}) \cdot P(\Theta \mid \mathcal{G}, \mathcal{D}).$$

Structure learning consists in finding the DAG with the best

$$P(\mathcal{G} \mid \mathcal{D}) \propto P(\mathcal{G}) \cdot P(\mathcal{D} \mid \mathcal{G}) = P(\mathcal{G}) \int P(\mathcal{D} \mid \mathcal{G}, \Theta) P(\Theta \mid \mathcal{G}) d\Theta$$

which is known as score-based learning [10]. The alternative, constraint-based learning, uses tests following Pearl’s work on causality [24]:

$$X_i \perp \perp P X_j \mid S_{X_i, X_j} \Rightarrow X_i \perp \perp G X_j \mid S_{X_i, X_j}.$$
What are we assuming when trying to learn a BN? Typically that:

- observations are **independent** and there are **no missing values**;
- all variables are observed, that is, there are **no latent variables** introducing confounding in the model;
- we measure probabilistic associations (or rather, independencies) and we cannot necessarily interpret them as **causal**.

What happens if we relax these assumptions? Many extensions suddenly become possible, see [19] for a recent review. In this talk we will discuss:

- Learning BNs from **continuous-time** dynamic data [5].
- Learning BNs from data in which data have structure, such as **state-space** data and collations of **related data sets** [2, 21].

We will not discuss learning BNs from incomplete data, but we are making progress on that front as well [4].
Bayesian Networks: Definition and Assumptions

Continuous-Time Bayesian Networks

Bayesian Networks for Structured Data

Future Directions
Continuous-Time BNs (CTBNs) are a framework for modelling finite-state, continuous-time processes. Their graphical representation allows for natural, cyclic dependency graphs without having to specify a temporal granularity [17].

A CTBN consists of two components:

- A directed graph encoding conditional independencies.
- A conditional intensity matrix (CIM) $Q_{X_i | u}$ describing the evolution process of a variable with the parameters
  - $q_{X_i}$: a set of intensities parameterising the exponential distributions over when the next transition occurs.
  - $\theta_{X_i}$: a set of probabilities parameterising the distribution over where the state transitions.
Score-based learning was covered by Nodelman [17] in his original work on CTBNs. For constraint-based structure learning, we need a new definition of conditional independence [5]:

Let $\mathcal{N}$ be a CTBN with a graph $\mathcal{G}$ over $\mathbf{X}$. We say that $X_i \perp \perp X_j \mid S_{X_i,X_j}$ if $Q_{X_i \mid x,s} = Q_{X_i \mid s}$ for all values $x, s$ of $X_j$ and $S_{X_i,X_j}$.

Note that conditional independence is not symmetric in CTBNs! To test it we need to test two separate hypotheses:

- **Time To Transition**: independence of the waiting times ($q_{X_i}$), tested with an $F$ test to compare their exponential distributions.
- **State-to-State Transition**: independence of the transitions ($\theta_{X_i}$), tested with a two-sample $\chi^2$ test or a Kolmogorov-Smirnov test.

We test time-to-transition hypothesis first and then, if the null is rejected, the state-to-state hypotheses. If both nulls are rejected, $X_i$ and $X_j$ are conditionally independent.
Hypothesis Testing

Time to Transition [3]: given the exponential waiting times $q_x|s$, $q_x|y,s$,

$$H_0 : \frac{q_x|s}{q_x|y,s} = 1 \quad \text{with null } F_{r_a,r_b}$$

where $r_a = \sum_{x' \in X_i} M_{xx'|y,s}$ and $r_b = \sum_{x' \in X_i} M_{xx'|s}$.

State-to-State Transition [15]: given $\theta_x|s$, $\theta_x|y,s$,

$$H_0 : \theta_x|s = \theta_x|y,s \quad \text{with null } \chi^2 = \sum_{x' \in X_i} \frac{(K \cdot M_{xx'|y,s} - L \cdot M_{xx'|s})^2}{M_{xx'|s} + M_{xx'|y,s}}$$

where $K = \sqrt{\frac{\sum_{i=1}^{k} M_{xx'|s}}{\sum_{i=1}^{k} M_{xx'|y,s}}}$ and $L = \frac{1}{K}$.

We reject the (conditional) independence between the two nodes if at least one null hypothesis is rejected.
Given how different the definition of conditional independence is, we need to adapt the PC algorithm [6] to match.

1. Form a complete directed graph $\mathcal{G}$ over $\mathbf{X}$.
2. For each variable $X_i$:
   2.1 Set $U = \{X_j \in \mathbf{X} : X_j \rightarrow X_i\}$, the current parent set.
   2.2 For increasing values $b = 0, \ldots, |U|$:
      2.2.1 For each $X_j \in U$, test $X_i \perp \perp X_j | S_{X_i, X_j}$ for all possible subsets of size $b$ of $U \setminus X_j$.
      2.2.2 As soon as $X_i \perp \perp X_j | S_{X_i, X_j}$ for some $S_{X_i, X_j}$, remove $X_j \rightarrow X_i$ from $\mathcal{G}$ and $X_j$ from $U$.
3. Return $\mathcal{G}$.

We call this the Continuous-Time PC (CTPC) algorithm [5]. It has better structural accuracy than the score-based approach in [17], but both approaches are slow: they are only practical for less than 20 variables.

Bayesian Networks: Definition and Assumptions

Continuous-Time Bayesian Networks

Bayesian Networks for Structured Data

Future Directions
Network models broadly fall into two groups:

- **Social networks** in which nodes are associated with individuals and arcs represents their similarity, measured on the variables.
- **Graphical models** in which nodes are associated with the variables in the data and the arcs represent probabilistic associations measured on independent observations.

We often want to model both perspectives at the same time:

- In causal networks to measure the average treatment effect from **multi-centre clinical trials**, individuals treated in the same hospital and the treatment they receive are more homogeneous than those in different hospitals.
- In **gene networks** and multivariate **genomic association** models, similarity between the genotypes of individuals implies a similarity in their phenotypical traits.
- In **state-space data**, individuals close to each other in space are more likely to exhibit similar behaviour; and longitudinal measurements are more strongly associated within than between individuals.

Failure to properly account for the similarity between individuals artificially inflates the strength of the apparent relationships between the variables, resulting in dense biased networks.
Hospitals produce separate data sets which are then collated together for the analysis. Inevitable differences in their implementations of the clinical trial make those data sets related but not identical. We want to learn the BN as a hierarchical model that separates the shared average effect encoded by each arc from hospital-specific effects, pooling information across hospitals.

**Assumptions:** the structure of the BN is the same for all hospitals, but the parameters differ between hospitals. The assignment of each individual to hospital is known.

**The mathematical formulation:**
- a variational Bayesian score with a hierarchical prior [2];
- using mixed-effects models [21].
Thus we get the Bayesian Hierarchical Dirichlet (BHD) score:

\[
P(\mathcal{D} \mid F, \mathcal{G}) \approx \prod_{i=1}^{N} \prod_{f=1}^{|F|} \prod_{j=1}^{|\Pi_{X_i}|} \left[ \frac{\Gamma(s_i \tilde{\kappa}_{ij})}{\Gamma(s_i \tilde{\kappa}_{ij} + n_{ij}^f)} \prod_{k=1}^{|X_i|} \frac{\Gamma(s_i \tilde{\kappa}_{ijk} + n_{ijk}^f)}{\Gamma(s_i \tilde{\kappa}_{ijk})} \right]
\]

where \( s_i \tilde{\kappa}_{ijk} \) = the posterior mean of \( \alpha_{ijk} \) under the variational model.
The BHD score:

- has **better structural accuracy** when we are modelling related data sets;
- it gets increasingly better as the number of related grows;
- it gets increasingly better as the size of (at least some of) the individual related data sets grows.

However, **this approach is not flexible** because we need a separate set of mathematical derivations for each structured-data scenario and for each type of random variable. In this respect, a better alternative is to use **mixed-effects models** (LMEs) [7, 18] as the local distributions for the $X_i$:

- generalised linear mixed-effects models (GLMMs) can model all types of variables in the exponential family (binomial, multinomial, Poisson, Gaussian, etc.) but
- in practice they make us reintroduce some linearity assumptions.
In a Gaussian BN, each node $X_i$ has distribution

$$X_i = \mu_{X_i} + \Pi_{X_i} \beta_{X_i} + \varepsilon_{X_i} \quad \text{with} \quad \varepsilon_{X_i} \sim N(0, \sigma_{X_i}^2 I_n).$$  \hspace{1cm} (1)

Adding a grouping node $F$ like clinical trial centres would make it a conditional Gaussian BN in which we fit a separate linear regression for each data set $j$ identified by $F$:

$$X_i = \mu_{ij} + \Pi_{X_i} \beta_{ij} + \varepsilon_{X_i} \quad \text{with} \quad \varepsilon_{X_i} \sim N(0, \sigma_{ij}^2 I_{n_j}).$$  \hspace{1cm} (2)

A mixed-effects model that takes (1) and adds random effects for all $\Pi_{X_i}$

$$X_i = \mu_{X_i} + \Pi_{X_i} \beta_{X_i} + Zb_{X_i} + \varepsilon_{X_i}, \quad b_{X_i} \sim N(0, \Sigma), \quad \varepsilon_{X_i} \sim N(0, \sigma_{X_i}^2 I_n)$$

has the same form as (2),

$$X_i = (\mu_{ij} + b_{0j}) + \Pi_{X_i} (\beta_{X_i} + b_{ij}) + \varepsilon_{X_i},$$

but pools information across data sets much like BHD does [21].
If the data are just a single homogeneous data set, introducing mixed effects does not degrade performance.
If the data really are a **collation of related data sets**, introducing mixed effects improves both structural (SHD) and parametric accuracy (KL). The difference becomes more marked if the related data sets are unbalanced.
Statistical genetics has long used the random effects in mixed-effects models to encode population structure (that is, related individuals), using pedigrees or genomic data [1]. In the context of BNs, the foundational Genomic BLUP model becomes

\[ X_i = \mu_{X_i} + \Pi_{X_i} \beta_{X_i} + g + \varepsilon_{X_i}, \quad g \sim N(0, K), \quad \varepsilon_{X_i} \sim N(0, \sigma^2_{X_i} I_n) \]

where the kinship matrix \( K \) encodes the relatedness. If \( K \propto GG^T \), with \( G \) the matrix of the genotypes, this model is equivalent to a ridge regression, which is in turn equivalent to a random-effects model [9, 23]:

\[ X_i = \mu_{X_i} + \Pi_{X_i} \beta_{X_i} + Gb_{X_i} + \varepsilon_{X_i}, \quad \varepsilon_{X_i} \sim N(0, \sigma^2_{X_i} I_n). \]

Hence we can add the random effects \( Gb_{X_i} \) to a local regression as soon as one of the genotypes is a parent of \( X_i \) to implicitly incorporate kinship. (Or we can give up modelling individual genotypes and do it like [13].)
Dynamic BNs can model temporal data as vector auto-regressive processes by duplicating nodes across time points [16], spatial networks over a grid [12]. However, this is impractical when observations are irregularly spaced and spread over time. A mixed-effects model can incorporate spatial and temporal autocorrelation into local distributions using random effects similarly to kinship in statistical genetics models.

✔ Bayesian Networks for Structured Data
→ Future Directions
Bayesian networks are a fundamental tool in machine learning: they subsume many models [19] and handle incomplete data [4], continuous-time time series [5] and collections of related data sets [2].

What next?

- Making CTBNs into Markov decision processes [11, 22] to model as streaming health data where we administer medical treatments in real time.

- Incorporating all the computational tricks used in the statistical genetics literature [8, 14, 26] to speed up learning.

- A reanalysis of a complex environmental data set such as [25] to explore BNs with a spatio-temporal structure.
